

## Chapter 1 : Modules, Comments & pip

Let's write our very first python program.  
Create a file called hello.py and paste the below code in it

```
print("Hello World")
```

 → print is a function (More later)

Execute this file (.py file) by typing `python hello.py` and you will see Hello World printed on the screen.

### Modules

A module is a file containing code written by somebody else (usually) which can be imported and used in our programs.

### Pip

Pip is the package manager for python.  
You can use pip to install a module on your system.

→ `pip install flask` installs flask module.

### Types of modules

There are two types of modules in Python

- 1> Built in modules → Pre installed in python
- 2> External modules → Need to install using pip.

Some examples of built in modules are `os`, `abc`, etc.  
Some examples of external modules are `tensorflow`, `flask` etc.

## Using Python as a Calculator

We can use python as a calculator by typing "python" + ↵ on the terminal

↳ This opens REPL  
or Read Evaluate Print loop

## Comments

Comments are used to write something which the programmer does not want to execute.

↳ Can be used to mark author name, date etc.

## Types of Comments

There are two types of comments in Python

1. Single line comments → Written using #
2. Multi line comments → Written using ''' comment '''

## Chapter 2 - Variables and Datatypes

A variable is the name given to a memory location in a program. For example

a = 30

b = "Harry"

c = 71.22

→ Variables = Container to store a value.

→ Keywords = Reserved words in Python  
Identifiers = Class/function/variable name

### Data Types

Primarily there are following data types in Python

1. Integers
2. Floating point numbers
3. Strings
4. Booleans
5. None

Python is a fantastic language that automatically identifies the type of data for us.

a = 71

⇒ Identifies a as class <int>

b = 88.44

⇒ Identifies b as class <float>

name = "Harry"

⇒ Identifies name as class <str>

Rules for defining a Variable name → Also applies to other Identifiers

- A variable name can contain alphabets, digits and underscores.
- A variable name can only start with an alphabet and underscore.
- A variable name can't start with a digit
- No white space is allowed to be used inside a variable name.

Examples of a few variable names are :-  
harry, one8, seven, \_seven etc.

## Operators in Python

Following are some common operators in Python:

- 1> Arithmetic operators  $\Rightarrow +, -, *, /$  etc.
- 2> Assignment operators  $\Rightarrow =, +=, -=$  etc.
- 3> Comparison operators  $\Rightarrow ==, >, >=, <, !=$  etc.
- 4> Logical operators  $\Rightarrow \text{and}, \text{or}, \text{not}$

## type() function and Typecasting

type function is used to find the data type of a given variable in Python.

```
a = 31
```

```
type(a)  $\Rightarrow$  class <int>
```

```
b = "31"
```

```
type(b)  $\Rightarrow$  class <str>
```

A number can be converted into a string and vice versa (if possible)

There are many functions to convert one data type into another

```
str(31)  $\Rightarrow$  "31"
```

$\Rightarrow$  Integer to String Conversion

```
int("32")  $\Rightarrow$  32
```

$\Rightarrow$  String to Integer Conversion

```
float(32)  $\Rightarrow$  32.0
```

$\Rightarrow$  Integer to Float Conversion

... and so on

Here "31" is a string literal and 31 a numeric literal.

input() function

This function allows the user to take input from the keyboard as a string

`a = input("Enter name")`  $\Rightarrow$  If `a` is "harry", the user entered harry

It is important to note that  $\Rightarrow$  If `a` is "34" user entered 34  
the output of input is always a string (even if the number is entered)

## Chapter 3 - Strings

String is a data type in Python.

String is a sequence of characters enclosed in quotes.

We can primarily, write a string in these three ways

1. Single quoted strings  $\rightarrow a = 'Harry'$
2. Double quoted strings  $\rightarrow b = "Harry"$
3. Triple quoted strings  $\rightarrow c = '''Harry'''$

### String Slicing

A string in Python can be sliced for getting a part of the string.

Consider the following string:

$name = "Harry"$   $\Rightarrow$  length = 5

	H	a	r	r	y
	0	1	2	3	4
	(-5)	(-4)	(-3)	(-2)	(-1)

The index in a string starts from 0 to (length-1) in Python. In order to slice a string, we use the following syntax:

$sl = name[ind\_start : ind\_end]$

first index included

last index is not included

$sl[0:3]$  returns "Har"  $\rightarrow$  characters from 0 to 3

$sl[1:3]$  returns "ar"  $\rightarrow$  characters from 1 to 3

Negative Indices: Negative Indices can also be used as shown in the figure above. -1 corresponds to the (length-1) index, -2 to (length-2)

### Slicing with skip value

We can provide a skip value as a part of our slice like this:

```
word = "amazing"  
word[1:6:2] → 'mzn'
```

### Other advanced slicing techniques

```
word = "amazing"  
word[:7] → word[0:7] → 'amazing'  
word[0:] → word[0:7] → 'amazing'
```

### String functions

Some of the mostly used functions to perform operations on or manipulate strings are:

- 1> `len()` function → This function returns the length of the string

```
len("Harry") → returns 5
```

- 2> `string.endswith("xy")` → This function tells whether the variable string ends with the string "xy" or not. If string is "Harry", it returns true for "xy" since Harry ends with xy

- 3> `string.count("c")` → Counts the total number of occurrence of any character

- 4> `string.capitalize()` → This function capitalizes the first character of a given string.

5. `string.find(word)` - This function finds a word and returns the index of first occurrence of that word in the string.

6. `string.replace(oldword, newword)` - This function replaces the oldword with newword in the entire string.

### Escape Sequence Characters

Sequence of characters after backslash '\'. → Escape Seq. characters

Escape sequence character comprises of more than one characters but represents one character when used within the strings.

Examples `\n`, `\t`, `\'`, `\\` etc.

↙ ↘ ↙ ↘ ↙ ↘  
newline Tab Single quote backslash.
